Preface

Sediments originate in river basins through erosion processes and are transported in river systems in the direction of the coast, being the final sink. Thus land use, climate, hydrology, geology and topography determine the sediment supply and transport in rivers. In the river system temporary deposition can take place. Important in this respect are floodplains and lakes. In many regulated rivers, sediments are trapped behind dams and reduce the sediment supply downstream. Important impacted areas downstream are wetlands, deltas and harbours.

It is not only the quantity of sediment which affects downstream areas but even more so the quality of the sediments. In particular, the presence of contaminants like heavy metals, nutrients pesticides and other organic micro-pollutants have biological impacts on waterways, wetlands and estuarine systems. In addition, the removal of contaminated sediments from waterways and harbours, to ensure their navigability, imposes high costs for the regulatory and responsible authorities at the local level.

The European Sediment Research Network - SedNet\(^1\) - is a three year project, commissioned by DG-Research, which dealt with the science, policy and regulatory aspects of contaminated sediments. Several workshops were organised and the results of the various working groups are summarised in the annexes that can be found in the enclosed CD-ROM. The complete results will be published in 2005 by Elsevier as a series of four books.

This document gives a short, general overview of scientific, policy and regulatory issues on contaminated sediments; an overview based on the results of more than 15 workshops and 3 conferences organised by the SedNet network.

Phil Owens and Joop Bakker are greatly acknowledged for improving the UK writing.

\(^1\) Project acronym: SedNet; EC contract No.: EVK1-CT-2001-20002, EC 5\(^{th}\) RTD Framework Programme; key-action: 1.4.1 “Abatement of water pollution from contaminated land, landfills and sediments”.
Setting the scene

The management of contaminated sediments in Europe has been mainly the direct concern of authorities dealing with navigable waterways. So far, only in a few Member States has contaminated sediment been managed due to its impact on ecological quality of water bodies. Hence, this summary focuses on issues currently facing water and port authorities dealing with contaminated sediments. It also gives an overview of expected changes through the implementation of the EU Water Framework Directive and touches upon the more general issues of linking sediment quality and quantity. In order to provide more than just general information we focus on some of the more visible issues facing the biggest port in the world, Rotterdam harbour, but, however, also place these issues within the river basin perspective. As such it serves as an example for other basins in Europe who face similar issues, as the workshops of the SedNet network have clearly demonstrated.

Many water and port managers face the continuous effort of dredging in order to maintain the required water depth. Due to the virtue of having open connections to rivers, lakes and seas, suspended particles in the water column and bed load settle at places with low currents. Complicating this need for continuous dredging is the fact that the dredged material may be contaminated to a level that will restrict its beneficial use or relocation. So far, this problem has predominantly been treated as a local problem. In general, it is then concluded that sedimentation is a fact of life and that the sources of the contamination are numerous, historic, and cannot be tackled. The managers are left to solve their problem themselves, which is usually performed on a case by case basis. They have to find a place to put it in somebody's backyard or a costly disposal site, or they are obliged to use expensive technology to immobilise or remove the contamination. The dredged material manager is usually required to the costs of this. The polluter pays principle is far from being applied. The problem is left for the problem owner and there is no link to those that have caused it.

The reason for this situation is that the appropriate regulations very much focus on how to deal with the dredged material as a local end-of-pipe problem. That the same risk is present when nature moves and relocates the sediment seems to be of another order and is not considered. The problem starts when you move the sediment and as soon as you do you become the problem owner. In essence, however, the problem was already there and when you solve only the part that needs to be dredged you do not solve it all. In addition, this an end-of-pipe solution. If you do not manage the cause of the problem, it will remain and the next time you need to dredge, the same situation may occur again. This is exactly the reason why the thinking should shift from dredged material management to sediment management. To manage the cause of the local problem, it is first of all important to know where the sediment originates and what the dynamic processes are that transport the sediment to the dredging site. When the sediment is contaminated, the same needs to be carried out for the contaminants.

The port of Rotterdam has adopted this shift in thinking, because the port has to deal with enormous quantities of contaminated sediment that are delivered by the river that links the port to its hinterland: the River Rhine. Hence a basin scale approach was essential. Knowledge and understanding was developed on the contaminant sources and the pathways. Based on that knowledge, agreements on the reduction of the input of contaminants (up to 90%) were made with parties that discharged polluted effluents into the river and its tributaries upstream as far as Switzerland. Also awareness campaigns were organised to involve other stakeholders: to make them understand the relation between their behaviour in the Rhine catchment with regard to diffuse sources of pollution and the ecological status of the river, the North Sea and maybe their most favoured vacation spot in the Wadden Sea area. It was explained that the link between those
Contaminated Sediments in European River Basins

values is in the sediment. Water dilutes, but sediment accumulates and when it is contaminated, the potential problem accumulates.

But along with that, the ecological situation in the Rhine and the North Sea coastal zone has improved significantly. Remaining is the problem of the diffuse sources in which the historic contamination that is present in the Rhine basin, is a source that is becoming increasingly important. Even more now, since the risk of extreme river floods that may wash the hidden pollution into the water system once again, seems to have been underestimated in the past.

When the European Water Directive Framework came into force, it introduced the management of water on a river-basin scale. Respecting the fact that the elements in the system are connected and that efforts to maintain and improve the ecological status of water bodies need to be coordinated on that scale, risk management should be carried out and priorities should be set on that scale. It makes no sense when a downstream manager is extremely precautious while the upstream manager is very pragmatic and sets other priorities, or vice versa. Management constraints in the river basin and receiving coastal zone should be focused on actions that are most effective on the scale of the river basin including that of the coastal zone. Then money is spent well and the environment is served most effectively.

It is expected that in the wake of water within the Water Framework Directive, the sediment issue will appear more prominent on that agenda. Sediments and ecological status of water bodies are interconnected. Since Europe has a problem of historic contamination of sediments in all the developed areas and faces a lasting significant input of sediment, contamination due to diffuse pollutants needs to be understood in order to manage the associated risk. In line with the Water Framework Directive, this urges the development of European-integrated sediment management on a river-basin scale. When that is adopted it is only a matter of time for problems to be managed primarily at their origin in the catchment, instead of end of pipe at the receiving end. Certainly, there is still a long way to go, but it may be a relief for the “frustrated” dredged material managers that are associated with and held responsible for a problem that really is the problem of the European society. And the character of its solution primarily depends on the agreed upon environmental values of the rivers, lakes, estuaries and seas, respecting the links between those values and the willingness to manage the potential risk in a sustainable manner.

To conclude, the management of contaminated sediment is just one driver for the need to manage sediment at a river-basin scale. The massive erosion of fertile top soils in different parts of Europe and the new thinking in flood control measures, as accepting controlled flooding of areas adjacent to the river, also has consequences for the sediment budgets. Furthermore, the past-present-planned damming of rivers in Europe and the excessive extraction of sediments from river systems for use as construction material strongly affects sediment supply. These are additional drivers which have to be taken into account for integrated sediment management at a river basin scale.
Extended summary

Sediment

Sediment is an essential, integral and dynamic part of our river basins. In natural and agricultural basins, sediment is derived from the weathering and erosion of minerals, organic material and soils in upstream areas and from the erosion of river banks and other in-stream sources. As surface water flow rates decline in lowland areas, transported sediment settles along the river bed and banks by sedimentation. This also occurs on floodplains during flooding, and in reservoirs and lakes. Often the natural sedimentation areas are severely restricted e.g. because of embankments and the loss of flooding areas as a result of these embankments. At the end of most rivers, the majority of the remaining sediment is deposited within the estuary and in the coastal zone. Natural river hydrodynamics maintain a dynamic equilibrium, regulating small variations in the water flow and sedimentation by re-suspension and resettlement. In estuaries, sediment transport occurs both downstream and upstream, mixing fluvial and marine sediment as a result of tidal currents.

Its value

Sediment forms a variety of habitats and environments. Many aquatic species live in the sediment. Microbial processes cause regeneration of nutrients and the important functioning of nutrient cycles for the whole water body. Sediment dynamics and gradients (wet-dry and fresh-salt) form favourable conditions for a large biodiversity, from the origin of the river to the coastal zone. A healthy river needs sediment as a source of life. Sediment is also a resource for human needs. For millennia mankind has utilised sediments in river systems as fertile farmland and as a source of construction material.

Contamination

Sediment acts as a potential sink for many hazardous chemicals. Since the industrial revolution, human-made chemicals have been emitted to surface waters. Due to their nature many of these chemicals stick to sediment. Hence in areas with a long record of sedimentation, sediment cores reflect the history of the pollution in a given river basin. Whereas water quality at most places is improving, the legacy of the past is still present in sediments hidden at the bottom of rivers, behind dams, in lakes, estuaries, seas and on the floodplains of many European river basins. These sediments may become a secondary source of pollution when they are eroded (e.g. due to flooding) and transported further downstream.

Along the course of the river to the sea, transportation, dilution and redistribution of sediment-associated-contaminants occurs. Many, relatively small inputs, all complying with emission regulations, accumulate to reach higher levels by the time sediment reaches the river delta. In the estuary, uncontaminated marine sediments are mixed with contaminated fluvial sediments. This natural ‘dilution’ decreases contamination level in a gradient towards the sea over short distances, but does not alter the actual transported quantity of contaminants.

Despite regular sediment quality assessment by member states, a reliable estimation of the overall amount of contaminated sediments in Europe is hard to give. The main reason for this is the absence of uniformity in sampling methods, analytical techniques and applied sediment quality standards or guideline values. This causes a lack of inter-comparability. Typically, countries along the same river basin use different methods.
**Adverse effects of contamination**

Contaminants can be degraded or fixed to sediment components, thus decreasing their bioavailability. At a certain level contaminants in sediment will start to impact the ecological or chemical water quality status and complicate sediment management. In the end, effects may occur such as the decreased abundance of sediment dwelling (benthic) species or a decreased reproduction or health of animals consuming contaminated benthic species. Contaminated sediments remain potential sources of adverse affects on water resources through the release of contaminants to surface waters and groundwater. Furthermore, contamination adversely affects sediment management, as handling of contaminated material, e.g. in the case of dredging, is several times more expensive than handling clean material.

Clean sediment can also have environmental and socio-economic impacts. For instance turbidity and excessive sedimentation have a physical effect on benthic life, too much sediment in navigation channels requires costly dredging, and sedimentation behind dams decreases the economic lifetime of that dam. Furthermore, dams decrease the supply of sediment needed to support downstream wetlands, estuaries and other ecosystems. SedNet focussed on contamination issues, rather than on such sediment quantity issues.

For the assessment of contaminated sediment, there is not one ‘best’ method available. Each specific management question requires a tailor-made solution. Chemical analysis can be used to determine concentrations of selected, hazardous chemicals and then it can be checked if the concentrations exceed pre-defined standards or guideline values. The toxic effects of sediment on organisms can be tested by using bioassays. Through a field inventory the long-term impact on sediment biota can be investigated. These assessment methods (chemical, bioassay, field) are complementary by giving a unique answer that cannot be given by any of the individual methods by themselves. But each method also has its own unique drawbacks and uncertainties.

**Sediment management challenges**

Sediment management challenges and problems relate to quality and quantity issues. Quality issues relate to contamination, legislation, perception, risk-assessment, source control and destinations of dredged material. Quantity issues mainly relate to erosion, sedimentation, flooding, the effects of damming and the resulting morphological changes downstream. Often quantity and quality aspects are interrelated: the overall umbrella is the river basin.

**Quality issues**

Contamination is one of the main issues when managing dredged material. Besides complicating dredging activities per se it may pose ecological risks or risks to water quality. The relation between sediment quality and risks is complex and site specific, requiring assessment methods based on bioavailable contaminant fractions and bioassays rather than results based on the traditional total contaminant concentrations. The EU Water Framework Directive (WFD) does not specifically address sediment management. However, if sediment quality impairs the chemical or ecological status, remediation measures may be needed. The WFD offers an opportunity to further improve our knowledge about the relation between sediment quality and water quality and to harmonise quality assessment on a river basin scale.

Legislation for handling dredged material is complex, because dredged material is at the borderline of water, soil and waste policies. Legislation is developing by the implementation of European regulatory frameworks such as the EU Landfill Directive, the EU Waste Framework Directive and the WFD. These EU legislations do not (as yet) deal adequately with sediment.

Sediment and dredged material are mentioned in several guidelines, but an integrated approach is presently lacking. However, the WFD aims at source reduction which in the long term may lead...
to such an improvement in sediment quality that it allows unrestricted relocation or direct beneficial use. Next to the emissions of point and diffuse sources, a source of increasing importance in this respect is historic contamination, i.e. our legacy of the past.

Contaminated dredged material is not only a management issue in remediation projects, but also in maintenance dredging. Dredging is needed in order to keep waterways, that tend to silt up, suitable for shipping. The costs for the removal of excess sediment increases when it is too contaminated for unrestricted relocation. The port of Rotterdam dredges 20 million cubic meters of sediment each year, of which approximately 10% exceeds the quality standard. Europe-wide, the volume of dredged material is very roughly estimated at 200 million cubic meters per year. Port managers are concerned that they should bear the extra costs for managing contamination which is derived from contributions along the river basin.

End-of-pipe solutions are unavoidable for dredged material management. Depots for contaminated dredged material are large, expensive, lack public acceptance and are subject to complex legislation. Solutions like relocation at sea or placement on river embankments are the first options to consider, since they relocate the sediment back into the system, where it belongs. But this solution is acceptable only if the contamination is below strict standards.

Alternatives include treatment for beneficial use and controlled (confined) disposal. Treatment and re-use is politically encouraged, but is currently applied only at a small scale because of the higher costs compared to disposal and the lack of product markets. However in some cases treatment and beneficial use may be a competitive alternative for confined disposal. Confined disposal will remain the first choice solution for the time being. For the realisation of new confined disposal sites (both upland and sub-aquatic), public involvement and support are needed. In many cases the procedures are very time consuming (10-15 years) and/or the NIMBY syndrome complicates and often prevents their realisation.

**Quantity issues**

Quantity aspects were not a predominant part of SedNet activities. However, they were addressed in several of the workshops since they influence the flux of (contaminated) sediments in river basins. A selection of the issues which were discussed and which have to be taken into account in basin-wide management are:

- the use of sediments in river basins for construction materials with the result of reduced sediment supply downstream, river bed incision and the associated impacts on infrastructure (e.g. bridges etc.)
- changing land use and effects of increased erosion on agricultural soils in particular
- the effects of damming, reducing sediment supply downstream and resulting in morphological changes to floodplains and deltas
- damming and the temporal storage of upstream pollutants in the deposited sediment (legacy of the past), with the consequence of further transport downstream through erosion events
- flood control measures including controlled flooding of areas adjacent to the river impacting sediment budgets

Last but not least, climate change and its impacts on the hydrology at the river basin scale will affect sediment fluxes and should be anticipated in a sediment management plan.
Contaminated Sediments in European River Basins

**SedNet recommendations**

The main SedNet recommendations towards EU policy development, sediment management and research, respectively, are:

- Further develop and eventually integrate sustainable sediment management into the European Water Framework Directive
- Find management solutions that carefully balance the social, economic and environmental values and are set within the context of the whole river system
- Improve our understanding of the relation between sediment contamination (hazard) and its actual impact to the functioning of ecosystems (ecological status) and develop strategies to assess and manage the risks involved
1. Sediment

1.1. Introduction

Sediments originate in the catchment through erosion processes and are transported in river systems in the direction of the coast and sea, with the latter being the final sink. As such land use, hydrology, geology and topography determine erosion and transport processes. In the river system temporary deposition can take place. Important in this respect are flood plains and lakes. In many regulated rivers, sediments are trapped behind dams and reduce the sediment supply downstream.

Figure 1. The Catchment-Coast continuum. Flow of contaminants, water and sediment from land, through rivers to impacted areas downstream

Important areas downstream are wetlands, deltas and harbours. The amount and the quality of sediment in the low-lying areas of the river system and in the estuary, delta and coastal zone depend on the processes in the contributing catchment. Hence, impacts on and functioning of these areas have to be considered as being part of the catchment-coast continuum (Figure 1). This section deals with erosion, transport and deposition of sediments. In addition, the function of sediment as an economic and ecologic resource and its specific role in wetlands and flood plains are discussed.

1.2 Erosion and transport

Erosion

Natural erosion is generally the dominant source of sediment in rivers. However, changes in land use, started centuries ago, have increased the erosion process. Increased soil erosion causes an increase in sediment supply to rivers, and is also of concern for the sustainable use of soils for agriculture. Soil erosion affects large areas of Europe and it is estimated that about 17% of the total land area in Europe is affected (Oldeman et al. 1991). However, large differences exist in Europe, which reflect land-use, topography and hydrology. In fact enhanced erosion due to deforestation, agricultural activity, urbanisation and other land-use changes is one of the most important changes occurring globally at the Earth’s surface. In Europe this process has been very
Contaminated Sediments in European River Basins

gradual over the last few hundred years and in most regions this additional flux is presently limited. In the most extreme cases, soil erosion, coupled with other forms of land degradation, has led to desertification in some areas of the Mediterranean. In a sense open pit mining is man-made erosion, since it generates loose particulate matter (tailings) likely to be disposed of into river systems, stored on land or in tailings ponds where it may be eventually remobilised. Since the rate of soil formation is very slow, any soil loss of more than 1 tonne/ha/year can be considered as irreversible within a time span of 50–100 years (EEA 1998).

**Transport in the river system**

As soon as soil particles are mobilised and transported, they can be deposited at the plot scale, in slopes and piedmonts. A major proportion of the coarse material (> 2 mm) derived from mechanical erosion from the upper river course does not travel very far from its source except in mountains catchment or during extreme floods. As such there is a difference in the amounts eroded from soils as well as a time delay before the actual delivery to the main channel. In the channels the incision of the river bed can be a major secondary source of river sediment. Also, within the river system there is a continuous remobilisation of deposited material from the lateral erosion of alluvial deposits.

Natural sediment traps include lakes and floodplains during high water discharge. River bed deposition occurs during low flows but is not permanent. It may last for a few years for successive dry years particularly in the Mediterranean regions, but this deposited material is eventually remobilised and transported further downstream.

Sediment transport depends on the water discharge of the river system. However, for a given river catchment size there is often a large difference in the amounts transported. Often sediment transport occurs in pulses. This effect is most pronounced for smaller catchments (up to 500 km²), here 50-90 % of the annual sediment flux is transported during time periods of days to weeks. In the largest basins (exceeding 100,000 km²), this effect still occurs, but is far less pronounced. Hence small basins or tributaries of larger basins are more subject to pulses of sediment flux compared to the total sediment flux from large basins. This feature has to be taken into account for the transport of contaminants.

**Transport in estuarine and coastal environments**

In the estuarine zone most of the river borne sediment is deposited, and only a relatively small proportion of the fine sediment load eventually reaches the open coastal zone, where it eventually settles. In areas with limited tidal range and little or no off shore currents (such as the Mediterranean and Baltic) most of the sediment in the estuaries and deltas are of river origin.

In estuaries with large tides this balance of sediments is reversed and there is a very little export of fluvial material but on the other hand a net trapping of material originating from coastal and marine erosion. This net trapping of sediment from the marine environment results in major dredging activities to allow for continued access of waterways to shipping. These estuaries can be divided in three parts, based on the dominance of fluvial or marine processes.

In the fluvial or upper part, the fluvial sediments dominate. Although sediment quantities to be removed for navigational purposes may be low, they are often contaminated from point and diffuse sources in the catchment. In the middle estuary, there is a depositional area consisting of a mixture of marine and fluvial sediments. The ratio of marine to fluvial sediments in this area depends on the discharge characteristics of the estuary. Hence, as a result the quality of sediments in this part of the estuary can change seasonally. During periods of low discharge (such as summer), the marine sediments with their lower contaminant load dominate, although with higher discharge the fluvial sediments are transported further into the estuary and hence the
Contaminated Sediments in European River Basins

Contamination in the middle estuary increases. The deposition (trapping) of marine sediments is predominantly in the lower or marine estuary.

The regional classification of estuarine dredged material in contamination categories reflects this natural process of the mixing of marine (relatively clean) and fluvial sediments (polluted). Figure 2 shows this regional classification for Rotterdam harbour. The western port area in Rotterdam, where most of the dredging takes place, receives mainly clean sediments from the North Sea. Also, in the Humber estuary most of the estuarine sediment is not derived from the contributing rivers but instead derives from the marine environment. In fact this situation is predominant in many of the estuaries and harbours bordering the North Sea.

Figure 2. The classification of estuaries and the corresponding classification of dredged material (example Rotterdam harbour).

Impacts of damming on sediment transfer

Damming has become a practical necessity and has provided huge benefits to agriculture, industry and urban development. The report of the World Commission on Dams (2000) has highlighted the scale of human intervention of ecosystems by the construction of large dams. Dams, inter-basin transfers and water withdrawals for irrigation have fragmented over 60% of the world’s rivers and changed the sediment load of rivers to the coastal sea.

In Western and Northern Europe reservoirs can be found in many catchments depending on their main purpose: hydroelectric reservoirs are common in Scandinavia and in the Alpine range from France to Slovenia, as well as in medium-high mountains (Tatra, Carpathian). Reservoirs of various sizes have been constructed in the Vistula, Elbe, Seine, Danube and Humber catchments. However, the greatest density of reservoirs is found in the Mediterranean basin (Spain, Southern Italy, Sicily, Greece). New reservoir cascades are planned in Greece or on the lower Vistula. In the African or Asian parts of the Mediterranean basin (Algeria, Tunisia, Turkey) reservoirs are also very common.

These reservoirs are human-made sediment traps in which more than 90% of the sediment transport of an incoming river can be stored when the residence time of the water exceeds two months. For the impact of damming on the global water and sediment flux, quantitative estimates
have recently been made. Globally, large reservoirs intercept more than 40% of global water discharge and approximately 70% of this discharge maintains a sediment trapping efficiency of more than 50%. It is estimated that about 25 to 30% \((4-5 \text{ Gt year}^{-1})\) of the sediment flux to the coastal sea is trapped behind dams. One of the positive environmental effects is the trapping of contaminants associated with sediments and in this way protecting downstream areas. A case in point is the Vistula catchments, where damming traps contaminants from upstream industrialized areas.

![Figure 3. Tentative sediment budget for Europe (Owens and Batalla 2003)](image)

However, damming effects the hydrology and morphology of the river downstream. The sediment starved water causes rivers to degrade (downcut) into the river bed until a new equilibrium has been reached. The decrease in sediment supply also causes coastal zones to change from accretion to erosion, which affects coastal morphology. Resources like floodplains and wetlands are similarly affected.

### 1.2. Deposited sediments

**Introduction**

Once sediments become deposited in wetlands, flood plains, deltas and also in the bottom of lakes and reservoirs, they have important ecological, social and economic value (i.e. the functions of sediments). In the case of navigable waterways and harbours deposited sediment can have a severe impact on shipping and may require dredging.

Too little or too much sediment in the catchment-coastal sea system has impacts on its functions. Table 1 gives an overview on the functions of sediment and possible impacts of changes in sediment delivery. In the next sections some of these functions will be highlighted.

**Biology of sediments: Ecological function**

The bottom sediments of lakes, streams, ground waters and wetlands host an enormous diversity of biota (Palmer et al. 2000). Global biodiversity is estimated at more than 100,000 benthic invertebrate species, 10,000 species of algae and more than 20,000 species of protozoans and bacteria. Biodiversity in aquatic sediments is poorly known, particularly for the smallest biota. This group is difficult to sample, as it is microscopic and often lives deep within the sediment. Species richness of freshwater sediment biota varies considerably between wetlands (locally up to 1500 invertebrate species), lakes and streams (locally approximately 80 – 1000 species) and ground waters (locally 0 – 150 species). Local diversity also varies over time, with, for example, low diversity in streams during flood season and high levels of diversity across the entire year.

Figure 4. Location of above sediment and aquatic sediment habitats (pelagic = living in the water column, hyporheic = saturated sediment zone) (Palmer et al. 2000).

Figure 4 illustrates the location of habitat types that are considered above sediment and those considered as aquatic sediments. Sediment biota may be defined as those organisms living within, on or closely associated with aquatic sediment at some stage of their life. The distribution between ‘above’ and ‘within/on’ sediment, is not as obvious, especially not in high-energy streams and rivers where the distinction between the water column is less clear and more variable in time.

Because species-specific information is typically lacking for sediment biota, a functional group approach is useful for examining the interactions among aquatic sediment organisms and those living above sediment. Many aquatic sediment species are likely to play important functional roles in freshwater ecosystems. Sediment biota not only mediate biogeochemical transformations of global significance, but are essential to the maintenance of clean water, the decomposition of organic material (often added in excess to our water bodies), the uptake and transfer of materials including sediment-bound contaminants and primary production.
The species composition and distribution of sediment-dwelling organisms is influenced by several factors. Important factors are: water flow, sedimentation rate and water oxygen content (reduced flow, enhanced sedimentation and lowered oxygen content may reduce diversity), presence of aquatic plants (plants increase species richness and abundance), the quality and quantity of water input of plant litter (i.e. a food resource for benthic life), pelagic predators (e.g. by bottom feeding-fish and predatory invertebrates), planktonic algae and bioturbation (as it alters the flux of nutrients and oxygen in the water column).
Upland sediments: Wetlands

Rivers act as “sediment conveyor belts” (Morisawa 1985), which starts from the erosion of soils, landslides etc., towards their ultimate transfer to the coastal sea. In the river system itself sedimentation leads to a temporary but often long-term loss of suspended matter from the flowing water to the floodplain. Changes in land use, mining, urbanisation and industrialisation in the upstream river basin strongly affect the quantity and quality of the sediments delivered to river channels. Sediment throughput along a river stretch is a function of sediment load, flow conditions and retention in the river corridor, which together result in a substantial variability among and within rivers in Europe.

Sediment retention in the main channel of a river is often limited, and flooding events are more important and lead to reduced annual sediment transport due to sedimentation on floodplains. Depending on the extent of the flooding and the topography of the floodplain, sorting of the grain size of the deposited sediments takes place. Laterally, increasingly fine matter settles in backwaters and lower marshes and at greater distances from the main river channel. Longitudinally, finer particulates travel the furthest downstream. Vertically, graded soil profiles on floodplains show successive flooding events with fine material overlying initially deposited coarser gravels. This sorting generates spatial patchiness and gradients in soil structure and fertility, and hence creates a wide variety of habitats for biota in an attractive, heterogeneous landscape scenery.

Sedimentation also brings nutrients to the floodplain. Phosphorus is mainly carried in particulate form, but also nitrogen is provided in different forms to floodplain habitats. Dissolved forms of

Managed realignment (new coastal wetlands) and its role in management at the catchment level: The Humber Case

Wetlands are composed of sediments and require for their functions a continuous supply of sediments. Apart from their role as important habitats they provide a filtering function for nutrients (denitrification) and contaminants (heavy metal immobilization through sulphide formation) as well as a role in coastal protection (soft defence). A detailed study in the Humber investigated their role as part of the catchment-coastal sea continuum. This study looked at the cost of upgrading wastewater treatment plants, cost to farmers (loss of income) for implementing the Nitrate Directive versus the cost of creating additional wetland areas in the Humber estuary, which can also provide nutrient retention. In addition, the creation of wetlands will bring down the cost of additional hard defences (dikes) in the estuary against sea level rise. The criteria for nutrient reduction were the OSPAR guidelines.

The main outcome of this three year research study was:

- Managed realignment, if implemented on a reasonably large scale, could be an effective way of improving the water quality of the Humber estuary. In the scenarios outlined above, farming practices throughout the ca. 25,000 km² of the catchment would have to be radically changed in order to achieve reductions in concentrations of nutrients throughout the estuary comparable to those realised by creating 75 km² out of a total floodplain area of 900 km² of new intertidal area around the estuary and tidal rivers by realignment of flood defences.
- Measures to tackle diffuse nutrient pollution from agriculture are more cost-effective than upgrading/construction of tertiary treatment. This is particularly the case for nitrogen and may also apply to phosphorus.
- Managed realignment has a number of environmental benefits (habitat creation, carbon sequestration, etc) the value of which can more than offset the costs associated with this option and can result in substantial positive net present values.

This research study shows that sediments play an important role in the catchment-coast continuum, and understanding their functioning is an integral part of its management. In this case cost benefits could directly be assigned to: nutrient reduction, coastal defense and carbon sequestration. Apart from that, other values include the creation of valuable wetlands as well as a recreational area.

Contaminated Sediments in European River Basins

nitrogen will only be retained in stretches where flow is sufficiently low to allow for plant and algal uptake or denitrification. However, in certain systems like the Rhine nitrogen is mainly carried as dissolved nitrate, and retention is negligible.

The highest sediment deposition rates are generally found where flow is reduced, such as in reed marshes (high surface roughness) or in deep ponds. Marshes, ponds and other depressions in floodplains therefore silt up comparatively rapidly, leading to vegetation succession and adding to spatial heterogeneity. In the floodplains of the River Rhine in the Netherlands contemporary sedimentation rates of overbank fines are estimated to be in the order of 0.5 – 3.5 mm per year (Middelkoop 1997).

River floodplains have attracted humanity well before the Neolithic because of the ample availability of natural resources, especially fertile soils and relatively flat land for agriculture. Early in history, river corridors also became pathways for trade and at least since the Roman era engineering works have been carried out to improve flow for navigation and an increase in safety from flooding. In The Netherlands, for example, a closed system of dikes existed along the branches of the River Rhine since about 1350 AD.

Large-scale embankment, however, concentrates flow and sedimentation into a narrow floodplain strip and aggravated flood consequences after dike failure. In addition, the main channel of the Rhine and many other larger rivers has been engineered extensively to maximize navigability as well as aid the transport of high water peaks. This has generally increased flow rates and hence the proportion of sediment that remains suspended.

Together with sediments, floodplain wetlands also receive particle-bound pollutants such as heavy metals. Middelkoop (1997) estimated for 1993 that 10% of the annual heavy metal load of the Rhine was deposited on its floodplains. A historical heritage of more heavy industrial pollution from the past is present in the soils of most central European river floodplains. This has led to concern for the breeding success of top predator birds such as the little owl (Athene noctua, Van den Brink et al. 2003) that largely feed on earth worms and voles.

In conclusion, sediments in river floodplain wetlands (a) serve as an important template for habitat differentiation through spatially variable sorting and settling, (b) contribute to the necessary nutrients to maintain a high floodplain productivity, and (c) allow for rapid autogenic succession and transitions between habitats.

Sand and gravel extraction

In lower and medium river courses the alluvial plain is the main source of sand and gravel extracted for construction of roads and buildings. This river material, which often corresponds in European catchments to sediment deposited some 10,000 to 6,000 years ago after the end of the last glacial period, is not regenerated today in most river catchments. In some catchments the present excavation of fossil sand is more than 50 times larger than the present river sediment flux, as for the Seine River (50 million tons excavated per year versus 700,000 tons transported by the river to the coast).

The total market for Europe has been estimated to vary between 2000 and 3000 million tonnes/year (Harrison 2003). This amount is in the same order of magnitude as the natural sediment delivery to rivers in Europe of 1800 million tonnes/year (Figure 3). Not all the sand and gravel is from recent deposits, and older sedimentary deposits in particular will often be mined. SedNet estimated that roughly 200 million tonnes is mined from fluvial active areas (Figure 3), which accounts to about 10 % of the total of sand and gravel mined in Europe.

Apart from its use as construction material for off-shore construction such as airports or harbour extensions, sand is also used for beach nourishment.
2. **Sediments and Contaminants**

2.1. **Introduction**

Contaminants enter the river system through various pathways. A distinction can be made between rural areas, urban areas and direct inputs. Input from rural areas is through erosion of soils, channel bank erosion, waste dumps and indirectly from atmospheric deposition on soils. Urban areas contribute through leaching from building material and from sewer systems. Direct inputs are derived from industry, shipping etc. (Figure 5).

![Catchment – Coast Continuum](image)

*Figure 5. The Catchment-Coast Continuum: a generalized overview of land use and pathways of contaminants.*

In this section an overview is presented on the various sources of contaminants, their transport, and their relationships with hydrological conditions. In particular the latter determine the contribution of the various sources and whether contaminated sediments remain in the riverbed or become more widely distributed over floodplains and wetlands. Furthermore, examples of the impacts of contamination are given and the assessment of contaminated sediment is addressed.

2.2. **Sources of contaminants**

A common distinction is between point and diffuse sources of pollution; a distinction which reflects their behaviour under changing meteorological conditions.

**Point sources** are identifiable points that are (fairly) steady in flow and quality (over the time scale of years). The magnitude of pollution is not influenced by the magnitude of meteorological factors. Major point sources under this definition include municipal wastewater effluents and industrial wastewater effluents.

**Diffuse sources** are highly dynamic and widely spread pollution sources and their magnitude is closely related to meteorological factors such as precipitation. Major diffuse sources under this definition include: surface runoff (load from atmospheric deposition), groundwater, erosion (load...
from eroded material, diffuse loads of paved urban areas (atmospheric deposition, traffic, corrosion), including combined sewer overflows since these events occur discontinuously in time and are closely related to precipitation.

Both point and diffuse sources contribute to the total contaminant load of rivers. A distinction between them is necessary for the planning of restoration actions and for the determination of the effects of past control measures at industrial sources. In rivers in Western Europe the contribution of point sources to total loads has decreased over the past decades and reflects the efforts of industry in combating pollution discharge. As a result the contribution from diffuse sources is becoming (relatively) more important. As an illustration of this trend the point and diffuse sources of mercury and lead in the Elbe are shown in Figure 6.

**Figure 6. Decreases and changes in the sources of mercury and lead in the Elbe basin.**

### 2.3. Transport of contaminants

**Transport in solution versus attached to the sediment**

Riverine material is characterised by a continuum of size from pebble to purely dissolved forms. The conventional definition of the “dissolved state” is that amount which passes a filter with a pore size of 0.45 μm.

“Dissolved compounds” are transferred across aquatic systems together with the water, while the “particulate compounds” are transferred differently: they may settle and be remobilised, according to flow velocity, particle size, river bed morphology etc. In river systems the pathways and transport characteristics of dissolved material and particulate material are therefore very different.

The fine and medium-sized particles, i.e. below 63 microns, are important. They consist of finely grained minerals like quartz, carbonates and feldspars. The finely grained clay minerals and organic matter are found in this grain size fraction. Often these finely grained particles are additionally coated with iron and manganese (hydro)-oxides. As a result of these coatings, their large specific surface areas, chemical nature and surface properties (organic matter), they act as efficient “scavengers” for contaminants discharged into the river system. When total suspended solids concentrations (TSS) exceed 100 mg/L, more than 90% of the most toxic metals, such as cadmium, copper, chromium, mercury, lead and zinc, and of major Persistent Organic Pollutants (POPs) such as the polychlorinated biphenyls (PCBs) and the poly-aromatic hydrocarbons (PAHs), are present in river particulates. Below 10 mg/L of TSS the dissolved fraction of these contaminants may equal or exceed the particulate fraction.
In European rivers the average TSS levels commonly range from 5 mg/L to 100 mg/L and more. During floods these levels are commonly multiplied by one or two orders of magnitude, which means that most metals, POPs and an essential part of organic carbon and nutrients are transported in association with the suspended particulate matter.

**Relationship with hydrological conditions**

The transport of contaminants is not constant with the discharge of a river system. Most data in this respect are available for heavy metals, and cadmium will be used to illustrate the relationship with discharge in the river Rhine.

![Graph showing the relationship between discharge and cadmium (Cd) concentrations in the Rhine.](image)

**Figure 7. Relationship between discharge and cadmium (Cd) concentrations in the Rhine**

The concentrations in the sediment, relevant for dredged material quality assessment and potential impact in sedimentation areas like wetlands, shows a complex relationship. At first the concentration in the suspended matter decreases, which reflects the dilution from relatively uncontaminated eroded material. This type of relationship was commonly found in monitoring data of 1970-1980 when the point sources were still highly dominant. Sediments deposited on the flood plains during high discharge had lower sediment contaminant concentrations compared to the concentrations in the river itself during normal discharge. In later years, the curve shows the relationship as depicted in Figure 7. With increasing discharge also the concentrations in the sediment increases. This is caused by the contribution of sediment from eroded contaminated areas, which contribute and now overshadow the input from point sources. It reflects the increasing importance of diffuse sources to sediment contamination in the river system.

### 2.4. Impacts of sediment contaminants

**Introduction**

Contaminants can be degraded or irreversibly bound to the sediment thus decreasing their bioavailability. Above this level, contaminants in sediment will impact the ecological or chemical water quality status and nearly always complicate sediment management. In this section some examples of such impacts are given.

**Effects on living organisms (ecological water quality)**

Research on several European rivers has demonstrated that sediment-associated contaminants can have adverse effects on sediment dwelling species. The abundance of certain species may decrease as a result of sediment contamination while other, more susceptible species may
disappear completely, resulting in a decreased biodiversity. A decreased abundance results in a decrease in food availability for higher organisms and, thus, a disruption of the aquatic ecosystem. Furthermore, through the consumption of ‘contaminated organisms’ the level of contamination can increase in organisms with each step in the food chain. Food chain transfer and bio-magnification may result in effects on reproduction or health of fish eating birds and mammals such as cormorants and otters. Consumption of severely contaminated fish (e.g., eel) or consumption of meat or milk from livestock on severely contaminated flood plains could also have an impact on human health. There are examples of floodplains where use by livestock has been restricted.

**Effects to water resources (chemical water quality)**

Even if we manage to significantly reduce or even stop the discharge of hazardous chemicals to rivers, substantial historic sediment contamination still remains. Through release of these contaminants to the surface and groundwater, these sediments remain potential sources of adverse affects on water resources (Figure 7). The present knowledge, however, is not sufficient to adequately predict the actual risks at specific sites.

**Effects on management**

Ports and channels need to be dredged regularly in order to keep them open to shipping, to allow a proper functioning of locks and dams (maintenance dredging), to prevent flooding and occasionally to restore or improve the quality of the ecosystem at a specific site (environmental dredging). Although the water and ‘new’ sediment quality is improving in some European rivers, a great deal of the older, deeper layers of sediment is contaminated to such an extent that disposal of dredged material to open water or land is not allowed and the beneficial use of this material, e.g. for the construction of dikes and soil improvement, is restricted. The dredged material must be disposed of in confined disposal facilities at much higher costs, or, when feasible, transformed into non-hazardous material, subjecting this sediment to costly treatments. Due to the enormous volumes involved, especially in the case of maintenance dredging in ports, minor changes in the management, or demands made upon dredged sediments, can result in dramatic changes in costs. More on sediment and dredged material management can be read in the next chapter.

### 2.5. Assessment of contaminated sediments

**Introduction**

Contaminants in sediment may impact the ecological or chemical water quality status. Some contaminants have the intrinsic possibility to cause such negative impacts and thus are hazardous. However, the actual risk of contaminants is to a large extent determined by their bioavailability. Strongly and in some cases irreversibly sediment-bound contaminants are hazardous, but their risk is negligible. Furthermore, even if ‘loosely bound’ sediment contaminants are or become available, e.g. due to bioturbation (i.e. resuspension of settled sediment due to activity of biota), or due to a flooding event, then there still is not a 1 to 1 relationship with impact to chemical or ecological quality. Thus it is very hard to predict whether or not a certain level of contamination will result in adverse effects on chemical or ecological water quality.

For assessment of contaminated sediment, there is not one ‘best’ method available. Each specific management question requires a tailor-made solution:

- Chemical analysis can be used to determine concentrations of selected, hazardous chemicals and then it can be checked if the concentrations exceed pre-defined standards or guideline values.
- The toxic effects of sediment on organisms can be tested by using bioassays.
- Through a field inventory the long-term impact on sediment biota can be investigated.

These assessment methods (chemical, bioassay, field) are complementary by giving a unique answer that cannot be given by any of the individual methods themselves. But each method also has its own unique drawbacks and uncertainties. A simultaneous application of these three, complementary assessment methods (Figure 8) is commonly referred to as the Triad-approach (Chapman 1996).

Chemical analysis (hazard assessment)

A major advantage of chemical assessment is its specificity. When a generally accepted standardised analysis procedure is followed, such as ISO, CEN, AFNOR, BSI or DIN (see glossary), the result will be an exact and reproducible amount for the analyses aimed for. By application of extraction techniques it is also possible to indicate the amount present in certain sediment fractions, such as the freely dissolved concentration in the sediment pore-water. Concentrations in such fractions may relate better to the amount that can impact the chemical or ecological water quality status. For such reasons it is also common to normalise data for organic matter or clay content, as it is well known that these decrease the availability of hydrophobic organic compounds and of metals, respectively.

If pre-defined quality standards are available (see for instance Den Besten et al. 2003) it is then very easy to check if they are exceeded and follow their implications for management. A very simple standard, for instance, relates to the ‘non-deterioration’ objective of the WFD: water, and thus also sediment quality should not deteriorate further. For the WFD priority hazardous substances that have a strong preference to stick to sediment, such as hydrophobic organic compounds, it makes more sense to monitor their trend or status in sediment instead of in the water phase. Trend monitoring provides an indication of temporal changes over a prolonged period, e.g. increases or decreases in concentrations of contaminants over time. Spatial monitoring will provide an indication of the status and variation of contamination over an area. Such monitoring is necessary to detect the spread of a contaminant over a river basin, and possibly to locate its source. It will provide basic information for appropriate sediment management. Historic contamination at hot spots is often reflected in the deeper sediment layers. The spatial variation in sediment contamination is influenced by differences in sedimentation rate.
of newly formed particulate material, as it influences the degree to which historic contamination is covered-up. Consequently, the choice of sediment sampling depth is a critical issue in mapping the status of sediment quality (Stronkhorst et al. 2004).

There are also some major disadvantages to chemical analysis. Results are only obtained for the contaminants aimed for and the use of quality standards has serious technical flaws. While the negative effects of some chemicals are relatively well-characterised, such as the toxicity of lead, others are not well understood, or may not even have been identified. Toxicity data are mostly derived from total concentrations in water tests only. It is well known that the bioavailability of contaminants in a whole water sample is profoundly decreased by the presence of suspended sediments. Furthermore, ecosystems may be able to adapt to additions of toxic chemicals, or changes in their environment.

**Bioassays (risk assessment)**

Over the years, research has demonstrated that contaminated sediments that exceed sediment quality guidelines do not always result in toxic effects in sediment toxicity tests or in the benthic community as a result of decreased bioavailability of the sediment-associated contaminants. Sometimes the opposite has been observed, i.e. sediment that meets a suite of Sediment Quality Guidelines (SQG) has caused adverse effects to the benthic community in the field or in laboratory toxicity tests because of combination toxicity or the presence of unidentified compounds. Therefore, in a growing number of European states, authorities are considering heading towards the implementation of bioassays in sediment or dredged material quality assessment procedures (Den Besten et al. 2003). Some countries already have implemented this, as is for instance the case in the Netherlands.

A bioassay may be defined as a laboratory or field experiment in which a selected aquatic species is exposed to sediment. If enough contaminant is available to the test species this exposure will result in a toxic effect. A toxic effect could be a reduced reproduction or growth or, in its most dramatic form, mortality (Brils et al. 1997). To date, several well standardised bioassays are available. Bioassays can range from using only a certain cell-type (or even part of that) of a test species to using several species in one test system.

As with chemical assessment, there are also disadvantages to bioassay assessment. A local sediment ecosystem is unique and comprises thousands of species. It is impossible to test for effects on all of them, and the degree to which tests on selected species can be extrapolated to others, or the ecosystem as a whole, is perhaps as difficult as extrapolating effects from chemical analysis. Furthermore, besides the effects mentioned above, there are numerous other effects that might occur, such as carcinogenicity, mutagenicity, endocrine disruption, changes in metabolism or role in ecosystem, etc. The mechanisms for these effects can all be different, but they can all have an impact on ecosystem health and function. It is impossible to test them all, so mostly a ‘battery of complementary bioassays’ is used in order to aim for different types of effect and/or use different test species. However, each addition to this battery means extra costs, so in most cases the number of different assays applied is limited to between 2 to 5.

Another complicating factor in applying bioassays is that whenever a toxic effect occurs the question of its cause will arise. An answer to that question is often required to be able to take the right measures, such as for instance to be able to address the source of contamination or to be able to select the appropriate remediation technique. For this purpose Toxicity Identification Evaluation (TIE) procedures have been developed. The goal of any TIE is to identify quickly and cheaply, as far as possible, those contaminants causing toxicity (Burkhard and Ankley 1989), thus TIE bridges the gap between the Triad components chemistry and assays (Figure 8). However, there are several examples where even an elaborate, and thus costly, TIE procedure was not
successful to identify the true cause of toxicity. On the other hand, several examples also exist where TIE was successful. For example, the endocrine disrupting compound TBT, that causes imposex at snails, was detected through such an approach. The mitigation measure taken is the global ban on the use of TBT on ship hulls (TBT is the toxic ingredient in anti-fouling paint, which prevents barnacles and other organisms to stick to ship hulls and thus to enhance fuel consumption).

**Field inventory (impact assessment)**

The third component of the Triad approach is field inventory, i.e. an assessment of taxonomic composition and abundance of benthic invertebrate fauna. These organisms, together with algae, serve as the most common biological water quality assessment indicators. The EC funded research project AQEM (AQEM 2002) has developed a benthic invertebrate-based assessment system for European rivers.

However, if a field inventory reveals a ‘poor or moderate status’ of benthic invertebrate fauna, e.g. indicated by a low diversity and abundance, then the question arises if and to what extent this status is due to an impact of sediment contaminants. This is a very challenging question, as the benthic invertebrate fauna status is to a large extent also determined by variables other than contaminants, such as habitat characteristics, the interaction between biota present, or the level of adaptation of benthic species to the contaminants present. Furthermore, what a field inventory reveals today is the result of what happened in the (near) past. Thus it could be the case that the sediment contaminant that actually caused the impact has already disappeared from the sediment due to degradation or erosion.

In order to help to bridge the gap between the Triad components assays and field inventory, use can be made of model ecosystems (Figure 8). However, model ecosystems incorporate both advantages and disadvantages involved with these extremes in terms of spatial and temporal scale. The main advantage of model ecosystem experiments compared to a field inventory is the opportunity to use replicated systems to test the response of perturbations. In contrast to a field inventory, the effects of a perturbation can be simultaneously studied and compared to an undisturbed system under similar environmental conditions. As is the case with all type of experiments, an optimal size of the test system and experimental duration should be chosen based on the hypothesis to be tested and on the desired level of complexity and reproducibility (Jak 1997).
3. Management of sediments

3.1. Introduction

Sediment quantity has been managed for centuries, mostly by dredging. This was, and still is, very much needed in order to keep waterways, that tend to silt up, open to the flow of water. This ensures a proper drainage capacity for precipitation and melting snow and ice, so it aids in flood prevention. But it also ensures water supply for drinking and irrigation purposes and for shipping. However, the natural hydrodynamic conditions of many waterways have been altered: directly by hydraulic constructions, such as dykes, dams, seawalls, and artificial drainage; and indirectly by changes in land cover and use, such as deforestation and urbanisation. These changes have resulted in the accumulation of sediment at places where the sediment impedes economic activities. The removal of sediments for the maintenance of waterways and water quality from locks, floodplains, harbours, navigation channels and river stretches is a high capital cost for responsible authorities and agencies.

These changes at the basin level are a major challenge to river basin managers and to the coastal zone managers who are 'at the receiving end' of the basin. Notable are the issues faced by port authorities, which have to deal with the sedimentation of riverine suspended solids in their ports. At the local scale the “dredged material manager” has to deal with navigability of water ways, which requires dredging, and with disposal issues in particular for those cases where the sediments are contaminated and exceed contaminant levels set by national or European regulations.

As a result, management of sediment operates at different spatial scales (Figure 9). The local managers (port authorities) have to deal with analysis, treatment and disposal aspects, which are guided by local regulatory guidelines, but also increasingly with European guidelines (Köthe 2003). Both PIANC\(^2\) and CEDA\(^3\) have developed guidelines for disposal of dredged material. In a wider context the local managers benefit from regulatory efforts for point and diffuse sources. Most often the point and diffuse sources are upstream from the dredging sites, and hence control of these requires management at the basin level. Point sources are direct discharges into the river systems by industrial activities, sewage treatment plants etc. Diffuse sources include agricultural activities, runoff from paved areas, erosion of (contaminated) soil and sewage overflows (Figure 5). Hence, European and national regulations on soil quality, prevention of erosion, implementation of sewage treatment, control of industrial point sources, indirectly are of benefit to sediment quality downstream. Sometimes contaminant

3 Central Dredging Association (www.iadc-dredging.com), see ‘read more’, section 6.3
control has to be carried out at the global level, which is the case for anti-fouling paints on ship hulls (TBT), for which measures have been implemented by the International Maritime Organisation (IMO).

Hence, sediment management follows different categories based on the spatial scale. At the small scale, regulators have to deal with the removal of sediments from waterways to, for example, allow safe navigation. At the basin scale, sediment management deals with both sediment quantity and quality. As such it is part of and benefits basin management schemes by dealing with the reduction of point and diffuse sources of contamination and erosion control. With regard to the quantity of sediments, the impacts of damming on sediment fluxes is well studied. However, the impact of the decrease or increase in sediment loads downstream on wetlands, floodplains and riparian systems should be an important part of sediment management at the basin scale. In preceding sections this issue of quantity has already been addressed. A special case of sediment management deals with “environmental dredging”, which means the removal of contaminated sediment solely for restoration of impacted aquatic ecosystems.

### 3.2. Local Management: Contaminated sediment treatment and disposal methods

If sediment cannot be relocated within the natural system, for example if it is too contaminated, disposal or treatment may be an option. Guidelines are available from trade organisations like CEDA and PIANC (see ‘read more’, section 6.3). Different treatment and disposal technologies are well known. On the one hand, there are world-wide experiences with handling and treating sediments. On the other hand, in many cases the experiences of the soil treatment and soil remediation industry as well as mining industry have been useful after adaption for sediment treatment.

The decision whether a given technology is applicable, depends on different factors. For instance, the chemical-physical characteristics of the sediment itself defines whether a process is applicable or not. The physical condition of the sediment has to be taken into consideration when a special technique is chosen, e.g. the grain size distribution. Nevertheless, if there is contaminated sediment, in many cases there will be a relation between the grain size distribution and the contamination of the sediment. Different investigations have shown that the content of heavy metals and organic contaminants is primarily governed by the grain size. The finer the particles and the higher the content of organic matter in the sediment, the higher will be the content of contamination.

Next to the costs, the main factors that determine the applicability of technologies are the properties of the sediments and the possibilities for beneficial use (including the use of sediment or treatment products as building materials).

Another important issue for the cost-benefit evaluation is the “market” for the beneficial use. To make a treatment method successful, it is important to have a market for the treatment products. However, it should be realized that the materials from treatment processes have to compete with conventional “natural” materials on the market. Often there is a cost disadvantage for the treated materials (AKWA 2000).

It is evident that by applying simple (relatively low-cost) technologies such as sand separation, land farming, ripening and stabilization, only a limited amount of dredged material can be processed into usable products, while by applying more advanced (relatively expensive) technologies, such as thermal immobilisation, more heavily contaminated sediments and residues from sand separation can be processed.

Of great importance are the costs of the different treatment options. They depend very much on the local circumstances. It should be noted that depending on the circumstances (e.g. sediment
composition, scale, disposal costs) large variations in costs occur. For example the costs for sub-
aquatic disposal facilities are lower for large-sized confined disposal sites.

![Figure 10 - Ex-situ thermal treatment costs-overview compared to costs for disposal and
relocation (LWA=Light Weight Aggregate; SAD=Subaquatic Disposal).]

Simple technologies such as sand separation and land farming / ripening are in general slightly
more expensive than disposal, while costs for stabilisation and thermal immobilisation
technologies are substantially higher. A summary of the ex-situ treatment costs are reported in
Figure 10. Compared with the costs of relocation all other sediment destination options are nearly
an order of magnitude more expensive. This again highlights the importance of source control at
the catchment level.

3.3. Long-term sediment management: catchment approach

Sediments originate in the catchment through erosion processes and are transported in the river
systems in the direction of the coast. Thus land use, climate, hydrology, geology and topography
determine the amount and timing of sediment delivery to rivers. In the river system temporary
deposition can take place. Important in this respect are floodplains and lakes. In many regulated
rivers, sediments are trapped behind dams and reduce the sediment supply downstream. Important
impacted areas downstream are wetlands, deltas and harbours. The amount and the quality of
sediment in the low-lying areas of the river system and in the estuary, delta and coast depend on
the socio-economic activities and the biophysical conditions in the contributing catchment.
Impacts on and functioning of these areas cannot be considered in isolation, but must be viewed
as part of the catchment-coast continuum (Figures 1 and 11). Another important aspect is the
delayed response of the downstream areas upon changes in sediment supply. In Europe the
reduction from pollution through point sources and diffuse sources have also shown a temporal
delayed response before this resulted in sediment quality improvement. Because of the slow and
delayed responses of both sediment quantity and quality, sediment management by nature is a
long-term process and has to be carried out at the catchment scale. Science has to provide the
necessary tools for catchment sediment management which are able to answer “what-if”
questions.

However, a catchment is a slowly responding geomorphologic entity, subject to socio-economic
catchment activities at a much faster pace, a combination which the dredged material manager has
to act on a daily basis to keep waterways navigable: a “spatial and temporal” challenge for
management which requires adequate scientific tools.
Emphasis in the preceding sections has been on contaminated sediments at a specific site. Many tools are available to access their impact and techniques are available for their disposal taking economic and environmental aspects into account.

In chapter 1 we addressed the quantity aspects of sediment generation and subsequent transport to the important sedimentation areas. A major proportion of eroded sediments are temporarily stored in (human-made) lakes, weirs, locks and floodplains before being transported to the coastal zone (see Owens and Batalla 2003). Although no comparable data are available for Europe, it has been estimated for the large river basins in the US that the material transported by rivers is only 10% of the erosion in the 20th century. This demonstrates that 90% is temporally stored between the “soil and the coast” (Syvitski et al. 2004).

Hence, science has to deliver not just sediment transport models, but models which are able to interface with erosion models, deal with temporal storage effects and interface with morphological models. The latter is important with regard to depositional areas like floodplains and wetlands. The current GIS (Geographic Information System) based modelling approaches allow for this kind of integration.

Such a suite of coupled models makes it possible to predict changes in erosion, sediment transport, deposition and morphological changes. The next question to be answered is a “what-if” one in order to make future socio-economic activities and regulatory activities transparent. Figure 12 shows clearly that many regulations and policies exist and are planned which will have impacts on the quality and quantity of sediments in a given river basin. These regulatory activities deal with discharges of pollutants and hence affect the quality of the sediments. They have to be translated into inputs for the “GIS-based” models to assess the temporal delayed responses and show when they become effective. A further case in this point are land use changes due to globally changing trade patterns and policies like the CAP (Common Agricultural Policy) which indirectly effect erosion and supply of sediments to the river system.

Climate changes are expected to change regional hydrology at the catchment scale and cause changes in erosion, transport and deposition of sediments. Tools for catchment management also have to incorporate the likely effects of climate changes on erosion, transport and deposition.
The discussion shows that many drivers and pressures have to be taken into account to predict future quality and quantity of sediments in a given catchment, a prerequisite for setting up a sediment catchment management plan. Last but not least a socio-economic assessment will be necessary to identify and quantify any negative and positive impacts on the environment (wetlands, floodplains etc.), economy or society at large.

One tool that can be used to answer these complex interactions and make them transparent is the use of scenarios for the catchment scale. Many global and European scenarios are available (IPCC, OECD etc.) which can be downscaled to the catchment level. Plausible land use changes, hydrological changes, etc. can then be interfaced with natural science and socio-economic models to assess the impact on (changes in) sediment quality and quantity. Based on these results and in strong consultation with stakeholders (see next section), choices can be made for implementing a catchment sediment management plan. Appendix C gives results of the use of scenarios to predict the future quality of sediments in the Rhine catchment.
4. Policy and regulations

4.1. Current regulations and conventions

There are a number of international and national conventions and regulations dealing with sediments, and in most cases with its quality (e.g. dredged material). They are listed below.

International conventions

Conventions of relevance for sediment management in Europe are:

Their purpose and primary aim is the environmentally sound disposal (relocation) of dredged material into the sea. Special national guidelines provide assessment criteria for the aquatic disposal (relocation or confined) for inland and coastal waters. Whereas the coastal guidelines are in line with the guidelines of the international conventions, national guidelines and criteria may differ for the inland part of the rivers. Due to national implementation of international conventions and EU Directives, the European member countries have developed special dredged material guidelines with different (limited) competences in practice.

European soil legislation

A European regulation for the protection of soils is under discussion as part of the EU Soil Thematic Strategy, which may include sediment-related issues. In addition, some European countries have already set Soil Protection Acts into force. For example in The Netherlands sediments (sub-aquatic soils) are part of the Dutch Soil Protection Act, in Germany they are excluded. The soils on the floodplains, often showing the same characteristic of contamination as the sediments in a river basin (due to flood events), are also under the scope of soil protection legislation. Furthermore, a goal of soil protection is the avoidance of soil erosion, which means prevention of increased introduction of suspended matter into the river.

European Waste legislation

The European Waste Directive (75/442/EEC, Article 1a) defines: "Waste" means any substance or object which the holder disposes of or is required to dispose of pursuant to the provisions of national law in force. Furthermore, the European Waste Catalogue (2001) contains two waste codes for dredged sediment:

- 170505 "Dredging spoil containing dangerous substances"
- 170506 "Dredging spoil other than those mentioned in 17 05 05"

This definition is independent on the contamination of sediments. The waste legislation follows the principle: 1. Avoidance of waste – 2. Beneficial use (incl. treatment) – 3. Safe disposal. All three options have to be part of an integrated sediment management. Several technical guidelines
in waste legislation apply to sediments and differ to some extent on the national level. The European Landfill Directive (1999) has to be applied if dredged material has to be disposed on land.

Figure 12. The Catchment-Coast continuum and some of the upstream and downstream regulations and policies effecting sediment quantity and quality as well as those relevant for impact assessment downstream.

4.2. The Water Framework Directive

Land-water interactions such as land use, land erosion and related sediment fluxes are subject to several environmental and sector policies. The inheritance of too many sector-orientated policies obstructs sustainable land-water interactions at the catchment level. In Europe for instance, agricultural land use is strongly influenced by the Common Agricultural Policy (CAP). The recently adopted Water Framework Directive (WFD) (2000/60/EC) is an attempt to provide a more integrated approach to water management at the river basin level. However, it is still unclear how the European Habitat Directive or Natura 2000 will be incorporated in this new Directive. The inclusion of land-water transition zones, like wetlands is also not clear.

First indications of the designation of water bodies in European river basins as required by the WFD suggest that their inclusion and classification differs widely across Europe. Although the WFD provides a list with priority substances, sediment fluxes are not explicitly included, even though sediment fluxes have significant impacts on water quality. Hence, there is a clear need for a more coordinated and integrated approach to manage land-water interactions through specific, tailor-made policy at the catchment level, including river basin-coastal zone interactions. The European Water Framework Directive may play an important coordinating role in this as it appears to have a legitimate legal basis to facilitate this process, but much will depend on the actual implementation process in the near future in individual Member States.
However, the WFD does not specifically address "sediment" and "dredged material" management, although sediments are a natural and essential part of the aquatic environment and their management has to play an important role within water legislation. Article 16 of the WFD provides strategies against water pollution. Article 16(1) requires the adoption of specific measures to progressively reduce discharges, emissions and losses of priority substances, and to cease or phase out discharges, emissions and losses of priority hazardous substances. This provision can help tackling existing pollution sources in European River Basins to reduce ongoing sediment contamination. Currently, several working groups within the implementation process of the WFD are paying increasing attention to the sediment issue.
5. Developments in sediment management

5.1. Introduction
The implementation of the WFD will shift the scope from local sediment management (e.g. dredged material) to river basin scale sediment management. In the opinion of SedNet this is a prerequisite and thus an important driver towards sustainable sediment management. It also drives other developments towards sustainable sediment management such as the transition from hazard to risk based management and stakeholder involvement.

5.2. Changing perspective on sediment as driver towards sustainable management
Building on the previous chapters, it is clear that:

- Sediment is an essential, integral and dynamic part of river systems, so it is obvious that there is a direct link between:
  - sediment quality and ‘ecological potential’
  - sediment quality and ‘surface water chemical status’

- Sediment is not tied to a particular area and is transported through countries in the same river basin

This changing perspective on sediment management is an important driver towards a more sustainable management of sediments. Contaminated sediment management issues and problems as addressed in the previous chapters should no longer be regarded as an ‘end-of-pipe’ issue, but as a common issue to all within a river basin who are responsible for that contamination. Thus trans-boundary management is needed for river systems that cross water bodies and national borders.

Furthermore, stimulated by the WFD, the view on sediment is changing to the recognition of the key role that sediment plays in the natural functioning of river systems. It is realised that the contamination issue cannot be viewed in isolation, but that sediment contamination has an impact on all parts of the soil-water system. Sediment management should fit in the holistic view on the role of sediment in river basin systems. This is similar to the policy development for contaminated soil. There, development also started with the perception that soil, like sediment, is a vital part of our environment that deserves protection by proper management (Vegter et al. 2002). The big difference, however, is that contaminated soil is a site-specific issue, while the mobility of contaminated sediment makes it a river basin issue.

5.3. Other developments related to sustainable sediment management

Transition from hazard to risk based management
In the previous chapters it is already addressed that contamination is a main problem when managing sediment and dredged material and that the relation between concentrations of chemicals (hazard) and their impact to water quality is complex and site specific. Assessment methods form the basis for decisions on remediation. The WFD offers an opportunity to harmonise assessment methods on a river basin scale.

Consensus is growing that contaminated sediment can be better assessed by looking at actual risks or impacts of the contamination, rather than on checking whether pre-defined sediment quality standards are exceeded. Thus a transition should be made from hazard- to risk-based management.
In the opinion of SedNet, the actual impacts of sediment contamination on the chemical or ecological status should be the determining factor for deciding whether intervention in sediment quality is required. Thus SedNet also agrees with the EU WFD Expert Group on Analysis and Monitoring of Priority Substances (AMPS) (Stronkhorst et al. 2004) that compliance monitoring of sediment quality is not recommendable. International organisations such as the International Council for the Exploration of the Seas and the OSPAR Convention (the latter having jurisdiction landward as far as the freshwater limit on estuaries) have given consideration to the question of environmental criteria for sediments for more than 20 years. Indeed, the WFD itself recognises the importance of such initiatives. These international organisations have concluded that quantitative environmental quality standards, derived from limited toxicological data, should not be employed as compliance criteria in complex natural systems. Notwithstanding this, ‘guidelines’ can be effective as part of a tiered risk assessment approach, e.g. to prioritise sites that need further/deeper investigation.

**Stakeholder involvement**

Design and implementation of (sustainable) sediment management, whether at the local, regional or national level requires the input from stakeholders. The involvement of stakeholders in environmental policy development and implementation processes will become more and more important. In fact, it is legally required due to the Århus-convention, the Water Framework Directive (WFD 2000) and the Directive 2003/35/EC of the European Parliament and of the Council of 26 May 2003. Besides that, resistance from stakeholders can prolong the decision process and increase costs and efforts on the long term. These negative aspects can be prevented, if stakeholders are involved in the decision-making process at an early stage.

EU regulations are not the only argument for stakeholder involvement. Apart from the basic fact that some stakeholders have an impact on the quality and quantity of the sediments, the two most important arguments for involving stakeholders are:

1) The obstructive power that stakeholders have. To illustrate this, a disposal site for dredged material always alarms citizens living near the site: please “Not In My Back-Yard” (NIMBY). They can, and often do protest against it, or take other actions. The early involvement of stakeholders reduces the risk of measures being delayed, or policies not being carried out.

2) The enrichment of the process, by inviting relevant stakeholders to obtain and apply knowledge and information supplied by them (Fischer 2000). No one can provide as much local insight to aid planning for the development of a disposal facility for dredged material as the local dredging companies, the people living in the vicinity of the site and the pressure groups that work to protect the natural and human environment in the area (Gerrits and Edelenbos 2004).

The United States Environmental Protection Agency (US EPA) has also embraced the concept of stakeholder involvement. When explaining their motivation for stakeholder involvement the US EPA specifically refers to the OECD publication by Caddy and Vergeze (2001) who state that: "Engaging stakeholders in policy making is a sound investment and a core element of good governance. It allows governments to tap wider sources of information, perspectives and potential solutions, and improves the quality of decisions reached. Equally important, it contributes to building trust in government, raising the quality of democracy and strengthening civic capacity."

It should be clear that ‘the public’ does not exist. The public is made up of numerous groups of people, not only citizens, but also of, for example, companies, governmental and semi-
governmental organizations and pressure groups. Stakeholders may be described as “persons, groups and/or organisations that can affect or are affected by sediment management”. Stakeholder involvement is therefore "the early involvement of individual citizens and other organised stakeholders in public policy-making in order to explore policy problems and develop solutions in an open and fair process of debate that has influence on political decision-making” (Edelenbos 2000). The level of involvement can vary from informing the stakeholders about the decision-making process to co-production of solutions and co-decision made by the stakeholders.

Now the question raises how to mobilise the stakeholders? Too often, decision-makers feel that the majority of the potential stakeholders lack interest whereas some with strong, but specific interests dominate the agenda. So it is the duty of the manager to let stakeholders realise what’s in it for them. Furthermore, awareness and urgency should be created. This can be done by pointing out the drivers behind sediment-related issues. Finally, the fairly technical nature of sediment-related problems such as contamination and morphological change need translation. Laymen cannot be expected to understand what it is about and therefore communication must be clear and free of jargon.

More on this issue, including rough guidelines for stakeholder involvement, can be read in the SedNet book on “Sediment management at the river basin scale” that will be published by Elsevier in 2005 or also in the paper of Gerrits and Edelenbos in the Journal of Soils and Sediments (2004).
6. Recommendations

6.1. Introduction

SedNet focussed on understanding river system functioning and how to manage contaminated sediment and dredged material in a sustainable way. To put it in wording, SedNet prepared a “Strategy Paper” (www.SedNet.org). Following this strategy, specific management issues were addressed by dedicated SedNet Work Packages (WP). Top-level scientists and major stakeholders contributed to the workshops organised by each WP used to identify and review the current state-of-the-art in knowledge, to identify practical recommendations and to review research needs related to specific sediment management issues. New scenarios and concepts where debated and are currently further underpinned. A complete description, as well as proposed way forward, will be commercially available in four SedNet books, published by Elsevier in 2005.

The reports of the outcomes of the individual workshops can be found at the SedNet website. A synthesis of the WP discussions, and a list of the core-people that contributed to those discussions, can be found on the CD-ROM that goes with this document. Furthermore, three annual SedNet conferences (2002, 2003 and 2004) were used to put the WP discussions in a broader perspective and verify the WP conclusions and recommendations.

The main recommendations resulting from these SedNet activities are described in this section, each recommendation is followed by a brief motivation. Supporting background information can be found in the previous chapters and in the documents mentioned above. Recommendations are structured as follows:

- EU policy development recommendations
- Generic recommendations towards sustainable sediment management
- Specific management recommendations
- Recommendations towards sediment monitoring under the WFD
- Research recommendations

6.2. Recommendations towards EU policy, management and research

EU policy development

Further develop and eventually integrate sustainable sediment management into the European Water Framework Directive

At the level of the EU, sediment management is addressed fragmentarily and it is only covered by EU policies and directives for very specific issues. Effective protection and management of our sediment resources needs a more focussed attention. The WFD aims to harmonise water legislation in EU countries and focuses on the management of water at the river basin scale. Thus it gives the best possibility for integration of a more direct and less fragmented focus on sediment management. The WFD, therefore, represents an enormous opportunity and stimulus to come up with guidance for sustainable sediment management (SSM). The current scope of the WFD does not yet clearly cover this subject. SSM should eventually become an integrated part of the WFD.

Other recommendations are:

- Regulate the upland and in/under water disposal of sediment on an EU level. Sub-aquatic confined disposal of contaminated sediments is not foreseen in the EU Landfill Directive.
The European Landfill Directive does not take into account the special properties of dredged material and the resulting requirements. Contrary to conventional waste disposal, dredged sediments should be stored in an anoxic, sub-aqueous environment. Very often, due to the high content of fine-grained material, sediments have a very low permeability, thus ‘they seal themselves’.

- **Implement support to the beneficial use of sediments in EU legislation.** Beneficial use of sediments is a demand of EU waste legislation, but is hampered by costs and legal restrictions. The EU Landfill Directive asks for further elaboration of treatment techniques. If beneficial use of (treated) sediments has to be a future option, it has to get more support in legislation, for example by putting pressure on the use of natural resources, like clay pits. Furthermore, such use will also be promoted by more flexible standards for application of treated sediment.

**Generic recommendations towards sustainable sediment management**

*Find solutions in the context of the whole river system that carefully balance the social, economical and environmental values*

Sediment issues occur in temporal ( geological and seasonal cycles) and spatial scales (catchment area, river foreland, polder) which cross political and administrative boundaries. Yet boundaries tend to scatter sediment management responsibilities and in the end no single stakeholder or country feels responsible. Planning sediment management at river basin scale will urge co-operation between agencies and even countries.

At that scale joint methods and strategies should be developed for sediment and dredged material management that link to the EU WFD and to pilot projects on trans-boundary rivers. Such methods and strategies should preferably be shared between different basins so that we can learn from each other. It will also help to recognise the differences between basins. This will underline the need to develop tailor-made, realistic solutions towards the environmental and socio-economic management issues (see above) that are at stake at that specific basin, or more detailed solutions at specific sites in that basin. For instance the type of dredged material, and the type of contamination, varies considerably between basins and between specific sites within a basin.

Thus sediment and dredged material management needs to be integrated into existing frameworks at this scale, such as river basin management plans (see further below under specific recommendations). An integrated approach is needed from inland (upstream) to coastal waters (downstream). This approach should respect the national and EU policy targets and comply with legislation.

Other recommendations are:

- **Find solutions in increase the interaction with stakeholders.** The perception of sediment depends on a variety of roles, values and definitions and is influenced by stakeholder interests. In order to maintain a dialogue, definitions and terms used to describe sediment must be neutral and all-embracing, and sympathetic to stakeholder values and views.

- **Intervene in such a way that it does not result in unwanted impacts elsewhere in the river basin (up- or downstream), nor in and/or should not have an adverse impact in the future.** A basic understanding of the water system, its dynamics and of functions of the bordering areas (populations, industries, agriculture) is essential for an effective decision-making process.
• Look for integrated solutions that embrace the whole soil-water system. Sediment is part of the soil-water system. Management of sediments should be planned in the context of the soil-groundwater-water-sediment system (the subsurface).

• Look for solutions that respect natural processes and functioning. Management strategies for sediment should respect nature: working with nature, not against it. Thus it is crucial to use and improve our understanding of river system functioning and the role of sediment in the processes involved (see further under research recommendations). For instance, taking sediment out of the system can cause sediment deficits resulting in habitat loss and destabilisation of river system functioning. Therefore, sediment management must also consider the sediment balance and its dynamic role in the hydrological and geomorphologic processes within each river.

Specific management recommendations
Where necessary, supplement the River Basin Management Plan by a Sediment Management Plan based on simple and cost-effective approaches that are in line with the EU WFD.

The existing contamination of sediment may exceed the relevant quality targets and may lead to a widespread distribution of contaminants in rivers with a correspondingly widely increased sediment contamination level. This makes it necessary to concentrate (financial) efforts on the source of the problem, instead of undertaking costly measures provoked by sediment contamination. In general, source reduction measures would be overall the most economical, efficient solution. When the problem is not just local, or the source of contamination can not be reduced immediately, long-term management solutions with interim arrangements have to be developed.

Sediment management is necessary to ensure that the requirements governing utilisation of waters are met, and at the same time also to protect sediment as a natural element of waters. Completely natural waters which are not subject to human influence or requirements do not need sediment management. The WFD promotes management of river basins according to uniform criteria. Where necessary, the River Basin Management Plan should be supplemented by a Sediment Management Plan. It should take into account the underlying needs and represents part of an agreed maintenance plan, linked to the measures necessary to achieve the sediment quality targets aimed for. Such a plan should fit to the basic objectives and requirements of the River Basin Management Plan. The components of a Sediment Management Plan for a particular river basin should include the following (in no particular order):

• Action to reduce point and especially diffuse sources. Following the WFD requirements source reduction is needed to phase out priority hazardous substances and/or to prevent further deterioration of the sediment quality. In the opinion of SedNet, it should also ensure unrestricted relocation of dredged material in the river basin, including coastal waters. Thus the WFD has to be compatible to the Marine Strategy of the EU. Furthermore, source control should ensure beneficial use of sediments or dredged material, be it on land, in water, or in coastal waters.

• Evaluation and/or monitoring of sediment quality, in order to make inventories and to enable prioritisation

• Action to reduce soil erosion and sediment delivery to rivers (and associated contaminant input) and control the sedimentation processes

• Action to provide and maintain water depths, discharge conditions, the maintenance of wetland areas, shallow water areas and retention spaces, and clean-up measures
Contaminated Sediments in European River Basins

- Framework for the disposal of sediments in the water, i.e. relocation, or possibly sub-aquatic confined disposal
- Options for beneficial use of removed, and if necessary treated sediment, including the use on land

Other recommendations are:

- **Stimulate innovation to more efficient treatment technologies.** To date, treatment and (technical) beneficial use of sediments are too costly, especially when taking into account the often very large amounts of sediment that are required to be treated. The technology itself is not the problem, as a diversity of treatment technologies is already available, but innovation to more efficient technologies is welcome. If the (political) goal is treatment and beneficial use, additional funds have to be allocated and support is necessary. A (temporary) financial impulse is needed to stimulate the development of large-scale treatment. An increase of the budget for dredging is needed in order to compensate for the higher costs of treatment. Regulations on the side of demand for raw materials are needed in order to create markets for products of treated dredged material.

- **The actual impacts of contamination on the ecosystem rather than chemical assessment should be the determining factor for deciding whether remediation of contaminated sediment is necessary for environmental reasons.** Sediment quality assessment methods should be based on the available contaminant fractions, on bio-assays results and/or on the results of a field inventory instead of total contaminant concentrations. Thus a transition should be made from hazard- to risk-based management.

**Sediment monitoring under WFD**

*Develop guidelines for monitoring contaminants in sediment in agreement with the EU WFD Expert Group on Analysis and Monitoring of Priority Substances (AMPS).*

The frequency of sediment monitoring should be specified further, and could range from once or twice per year to once every 5 to 10 years depending upon the sedimentation rate. Sediment samples could be collected randomly at the designated sampling point and the location of each should be recorded. Samples shall be collected at the same time of the year for each sampling occasion, the time being chosen according to local circumstances, bearing in mind the aim of monitoring trends in the concentration of contaminants. The purpose of sediment monitoring guidelines is to assess long-term trends in impacts of anthropogenic pressure and to ensure no deterioration limit is reached and that comparable data are collected.

In case ecological criteria of the EU WFD are not met, a check may be needed on the role of sediment contamination. This requires sediment quality assessment approaches (cause-impact analysis) that can be linked to the WFD.

Other recommendations are:

- **SedNet recommends criteria to select the target compounds to be monitored in sediments.** The selection of target compounds to be monitored in sediments should be based on: 1) Persistence; 2) Bioaccumulation/adsorption; 3) Toxicity; 4) Relevance at the large scale (river basin); 5) High fluxes (tendency to increase concentrations/fluxes on a long-term basis); 6) Addition or replacement of pollutants will be based on the results of present and future monitoring programs and on the results achieved by RTD projects where the identification of new or emerging contaminants takes place.

- **Include sediments and/or suspended solids in river monitoring plans.** Substances which tend to accumulate in the geo-sphere and are transported bound to particles, may better be
measured in the suspended matter than in the water phase, which is particularly important for some new groups of compounds included in WFD, such as flame retardants (PBDEs). It is clear that transfer of contaminants from the sediments to the water column through processes of diffusion, advection and sediment resuspension is a major factor. SedNet recommends that a river monitoring plan should necessarily include monitoring of the suspended matter, in order to obtain an holistic picture of the contamination status of the whole river basin. In this respect, we should add that contaminants in suspended sediment generally represent “current” rather than historical pollution, as they will ultimately lead to “new” deposits of contamination and newly settled material is the main food source for detritivorous benthic organisms.

- Monitoring should include assessment of bioavailable fraction of contaminants, in both the laboratory and the real field situations. The relation between sediment quality and risks is complex and site specific, requiring assessment methods based on bioavailable contaminant fractions and bioassays results rather than on the traditional total contaminant concentrations.

**Research recommendations**

*Improve our understanding of the relation between sediment contamination (hazard) and its actual impact on the functioning of ecosystems (ecological status) and develop strategies to assess and manage the risks involved*

Over the years, research has demonstrated that contaminated sediments exceeding standard or guideline values do not always resulted in toxic effects in bioassay testing or in the benthic community. This is due to a decreased availability of the sediment-associated contaminants. Sometimes the opposite has been observed: sediment that met a suite of standard or guideline values caused adverse effects to the benthic community in the field or in bioassays because of combination toxicity or the presence of unidentified compounds. This demonstrates the need to better understand the relation between sediment contamination (a hazard) and its actual impact on the functioning of the ecosystem (ecological status). Wherever a poor diversity and abundance of benthic invertebrates is observed, the question will arise to what extent this is due to sediment contamination. A proper answer to that question is needed in order to be able to decide whether sediment remediation might help to improve that status.

Other research recommendations are given and motivated in the two dedicated SedNet documents that can be found at our website and at the enclosed CD-ROM. In summary, SedNet recommends:

- Especially in the context of perturbations due to climate change, improve our understanding, and thus also our capability to predict or model the fate of contaminants: from emission (upstream) to adherence to soil and/or suspended particles to sedimentation (also upland) and re-suspension (downstream).
- Improve our understanding of sediment transport processes (including erosion and sedimentation) at the river basin scale as a function of land and water use and hydrological (climate) change in Europe.
- Investigate new architectures for policy processes with respect to sediment and soil issues that enable the interaction of several involved policy domains, interaction with stakeholders, new joint knowledge production processes and joint actions.
- Investigate how the connection between the different involved policy levels and between strategy and implementation can best be established.
• Evaluate (social/economic/technical/environmental) source control programmes and to perform a cost-benefit analysis of risk reduction through source control, including the management of historic contamination.

• Downscale global, European and country scale socio-economic scenarios to the river basin scale and their effects on sediment quantity and quality and soil quality, and to stimulate research into the development of best management plans to comply with current and future EU regulations.

6.3. Read more
SedNet recommends the following reports, books or other publications to read more on the issues touched upon in this document:

Appendices (at CD-ROM)

The CD-ROM that is enclosed in this document contains the following appendices:

- Appendix A. Synthesis reports of the working packages (WP) of SedNet:
  - WP2. Sediment Management at the River Basin Scale
  - WP3. Sediment Quality and Impact Assessment
  - WP4. Sediment and Dredged Material Treatment
  - WP5. Sediment Risk Management and Communication

- Appendix B. Other publications from SedNet. Index:

<table>
<thead>
<tr>
<th>Ref. No.*</th>
<th>Type</th>
<th>Title</th>
<th>Authors</th>
</tr>
</thead>
<tbody>
<tr>
<td>M1.8.2</td>
<td>Brochure / newsletter</td>
<td>Sediment, a valuable resource that needs Europe’s attention</td>
<td>SedNet contractors and Stakeholders Panel</td>
</tr>
<tr>
<td></td>
<td>Paper</td>
<td>A first attempt to approximate Europe’s sediment budget</td>
<td>Owens &amp; Batalla 2003</td>
</tr>
<tr>
<td>etc.</td>
<td>JSS papers</td>
<td>&gt;&gt;&gt;to be completed&lt;&lt;&lt;</td>
<td></td>
</tr>
</tbody>
</table>

* Reference Number: where possible, the deliverable (D) or Milestone (M) numbers as related to the EC SedNet project (EVK1-CT-2001-20002) are used.

- Appendix C. Case Study: Future quality of sediments and the use of scenarios
- Appendix D. Treatment methodologies at the river basin scale
- Appendix E. Relevant publicly available documents:
  - Position Paper From CEDA on “River Basin Sediment Management from the viewpoint of Dredging Stakeholders”
  - Other documents from PIANC, Dutch-German Exchange an other relevant doc’s
- Glossary

>>>this CD-ROM is not yet enclosed, it will be enclosed in the final document only, reports and publications from SedNet are also already available through our website: [www.SedNet.org](http://www.SedNet.org)<<<
